

## LONG TERM FERTILITY EFFECTS

by

R. Kunkel

Washington State University, Pullman, Washington

A very comprehensive potato fertilizer experiment was started in 1965. The first objective was to determine the effect of the amount and ratio of N-P-K on blackspot. In as much as the cost of growing the crop was the major expense it was decided to obtain all the data possible which included yield, grade, specific gravity, chip color and soil, petiole and tuber analyses. In this report only changes in yield and effects on the soil will be included.

Each year the same fertilizer treatments were put on their respective plots (except as noted) to hasten depletion of nutrients in some plots and hasten excessive build-up in others by using what was thought to be excessive amounts of N-P-K. Because of the known cropping and fertilizer response records this little plot of ground has become more valuable experimentally with each additional year's results. The cropping history is in Table 1.

Four levels of N-P-K were combined in all possible combinations to make 64 fertilizer treatments. Each treatment was replicated six times. The exact amounts of nutrients applied each year are in Table 2. The nitrogen rates were increased in 1971 and 1972 because the yields of potatoes had become so low on those plots which did not receive fertilizer nitrogen. The same phosphorus and potassium rates of fertilization were maintained throughout. The total amount of each nutrient applied over the years is also shown.

The yield data for the potato and wheat crops are in Table 3. The detailed results were not included because the trends are more evident when the overall effects of N-P-K on yield and soil are considered. Potato yields were highest in 1965, the first year the land was planted to potatoes. Each year thereafter the yields decreased regardless of the fertilizer used. In the spring of 1967 the land was fumigated with the equivalent of Telone C but even this failed to restore productivity to its original level.

Table 1. Cropping History.

1965	First year in potatoes
1966	Second year in potatoes
1967	Third year in potatoes--fumigated with Telone C
1968	Wheat
1969	Wheat
1970	Potatoes--vines burned
1971	Potatoes--vines burned, fumigated, solid set sprinkler
1972	Potatoes--fumigated, solid set irrigation

1971	Potatoes	477	495	492	485	412	498	511	527	466	477	499	507
1972		508	487	499	505	460	499	514	526	454	475	532	538

The first year (1968) the land was planted to wheat there was a sizeable yield response from the residual N in the soil after the potato crops. The second year of wheat did not show the large yield response indicating the first crop of wheat depleted the soil of its residual nitrogen supply. No yield increases of wheat were obtained for either P or K. The low nitrogen status of the soil following the second crop of wheat is also indicated by the large increases in potato yields resulting from increasing amounts of fertilizer N in 1970. Increasing the amount of fertilizer P in the soil also increased the yield but fertilizer K did not.

The falls of 1970 and 1971 the potato vines were burned off and in the springs of 1971 and 1972 the land was fumigated with Telone C.

In 1972 the entire area was fertilized with 430 lb/acre of N from ammonium nitrate but no P or K was applied. The potatoes were irrigated by solid-set sprinklers. Thus it was expected that neither water nor disease would limit yield.

The yield data for 1972, Table 4, indicate that 430 lb/acre was ample N to grow the crop of potatoes but that the residual P and K levels in the soil from previous applications was insufficient for maximum production. The potato yields, nevertheless, were not equal to those obtained the first year the land was planted to potatoes.

A summary of the nutrients added in the fertilizer, the amount of nutrients removed in the crops, the theoretical balance of N-P-K left in the soil, the soil test values and the yields in 1972 are also shown in Table 4. The data for the effects on the land of adding such large quantities of fertilizer are in Table 5. The effects on the land in those plots which received the N treatments are shown in part A, those for P are in part B and those for K are in part C.

To date, insignificant changes have occurred in soil pH and salt content. The soil test level for P increased even on those plots which were not fertilized with P. Soil test P levels increased with increasing amounts of P added in the fertilizer. Soil test K levels increased at the two higher rates of fertilizer K application. It should be remembered, however, that the P and K accumulation would not have occurred if the potato yield levels had been as high as it was the first year the land was planted to potatoes.

K <sub>4</sub>	0	8.0	2.8	125	2000	7.8	25	190	.30
Mean	8.0	3.1	131	Mean	7.8	24	157	.29	

The loss in yield is not explainable on the basis of either disease, water or nutrition. A compacted soil layer about eight inches deep, through which roots were not penetrating, was observed in the experimental area. Such a layer not only restricts the nutrient and water reservoir but could limit the root oxygen supply which would reduce the roots ability to absorb both water and nutrients. Such layers are apparently not uncommon even on sandy soils.

The following conclusions seem justified:

1. It is evident from the data that fertilization alone did not maintain yields of potatoes equal to those obtained the first year the land was planted to potatoes.
2. Vine burning and soil fumigation to eliminate soil borne diseases did not restore the land to its original productivity though improved yields were obtained.
3. The critical soil test level for phosphorus should be increased above 10 ppm.
4. Cursory observations suggest that soil compaction might be responsible for the loss of yield since the plants were adequately irrigated, major and minor elements were adequately supplied and soil pathogens were reduced. This aspect of the problem is now being investigated.
